

1.1

Basics

A **graph** is a collection of vertices and edges with a given relation denoted $G = (V, E, R)$. Most of the time, we just use G to denote the entirety of (V, E, R) . A graph is **simple** if there is only one edge between two vertices, and there are no loops (i.e., an edge that connects a vertex to itself). We will be dealing with simple graphs for now.

Edges between two vertices u and v are denoted uv , and this edge is **incident** on two vertices. Two vertices are **adjacent** if there exists an edge between them. Adjacency is denoted $u \leftrightarrow v$.

Two graphs are equal if $E(G) = E(H)$ and $V(G) = V(H)$, while they're isomorphic if $\exists \varphi : G \rightarrow H$ such that $uv \in E(G) \leftrightarrow \varphi(u)\varphi(v) \in E(H)$ where φ is a bijection. This is similar to the definition of isomorphisms for groups and rings. An isomorphism class is the equivalence class of graphs under the isomorphism relation (this is akin to a graph without labeled vertices).

Complete Graphs and Subgraphs

Complete graphs are ones where every vertex has an edge to every other vertex. They are denoted K_n . An example of K_4 is shown below.

A **subgraph** is a graph H such that $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. For example, the following is a subgraph of K_4

An **induced subgraph** is a subgraph such that $E(H)$ is the set of all edges in G that connects vertices in $V(H)$. It is usually denoted $G[V(H)]$. For example, we can see an induced subgraph in K_4 selecting three vertices as follows:

Paths, Cycles, and Complements

A **path** is a nonempty graph in the form $P = x_1, x_2, \dots, x_k$ with edge set $E(P) = \{x_1x_2, x_2x_3, \dots, x_{k-1}x_k\}$, where edges don't repeat themselves. A cycle is a path where we include the edge x_kx_1 . We will learn about different kinds of paths, trails, etc. in section 1.2.

The complement of a graph, \overline{G} is found by using the same vertex set and taking the complement of the edge set. In other words, $V(\overline{G}) = V(G)$ and $E(\overline{G}) = \overline{E(G)}$. For example, we can consider the complete bipartite graph $K_{3,3}$ (explained later), and see its complement.

We can see that the complement is isomorphic to two copies of K_3 , which is the triangle graph.

A **independent set** is a set of vertices that are not adjacent to each other in G (implying they are adjacent to each other in \overline{G}). For example, the independent sets in the above graph of $K_{3,3}$ are those two sets of K_3 . The independence number $\alpha(G)$ is the cardinality of the largest independent set in G .

Similarly, a complete subgraph, also known as a **clique** is a subgraph of G where all the vertices are connected to every other vertex, implying that the clique is an independent set in \overline{G} . The clique number, $\omega(G)$ is the size of the largest clique. We can see that $\omega(G) = \alpha(\overline{G})$ and vice versa.

Partitions

A graph is **bipartite** if there exists a partition $G = X \sqcup Y$ (where \sqcup denotes the disjoint union) where X and Y are independent sets. A bipartite graph is **complete** if $\forall x \in X, \forall y \in Y, x \leftrightarrow y$. Complete bipartite graphs are denoted $K_{m,n}$, where m denotes the size of one independent set and n denotes the size of the other independent set.

Similarly, a k -partite graph is one where $G = V_1 \sqcup V_2 \sqcup \dots \sqcup V_k$, where V_i is an independent set for all $1 \leq i \leq k$. A k -partite graph is complete if every vertex in V_i is adjacent to every other vertex in every other V_i .

A **coloring** of a graph is a function $f : V \rightarrow S$ such that $f(v) \neq f(w)$ if $v \leftrightarrow w$. A bipartite graph is 2-colorable, and a graph is k -partite if and only if it is k -colorable.

Matrices

The **adjacency matrix** of a graph is a matrix defined as follows:

$$A(v, e) = \begin{cases} 1 & \text{if } v \in e \\ 0 & \text{if } v \notin e \end{cases}$$

The incidence matrix, on the other hand, represents the vertices on the rows and the edges on the columns — for a given row, a 1 is placed in a column for any edge the vertex is incident on. We can show that $A^2 = MM^T$ for adjacency matrix A and incidence matrix M for any given graph. The incidence matrix need not be square, but the adjacency matrix is necessarily square

- The sum of any given row in the incidence matrix is the number of edges incident with the vertex, or $d(v)$ (for degree).
- The sum any given column in the incidence matrix is 2, for a simple graph.
- The sum of any given row or column in A is the number of vertices adjacent to the vertex, once again yielding $d(v)$.
- We can show that $A^2 = MM^T$ for adjacency matrix A and incidence matrix M on any given graph.

The Petersen Graph

We can also examine combinatorial relations through graphs. For example, the Petersen graph (G_p) is defined as follows:

The simple graph whose vertices are the 2-element subsets of a 5 element set, and whose edges are the pairs of disjoint 2-element sets.

We can show a couple theorems using this definition of the Petersen Graph.

Propositions about the Petersen Graph

- Every vertex in the Petersen graph has degree 3.
- If two vertices are non-adjacent in the Petersen graph, they share exactly one common neighbor.
- The girth (or length of the shortest cycle) of the Petersen graph is 5.

Solution

Every vertex in the Petersen graph has degree 3.

Because there are 3 elements in $[5] = \{1, 2, 3, 4, 5\}$ not equal to any given set of two numbers, we know that the number of vertices adjacent to any given element is $\binom{3}{2} = 3$.

If two vertices are non-adjacent in the Petersen graph, they share exactly one common neighbor.

Suppose two elements $v_1 \neq v_2$ are in $V(G_p)$ where $v_1 \not\leftrightarrow v_2$. Then, it must be the case that $v_1 \cap v_2 \neq \emptyset$, meaning that $|v_1 \cap v_2| = 1$, and $|v_1 \cup v_2| = 3$, implying that $|[5] - v_1 \cup v_2| = 2$. There is only one $v_k \in V(G_p)$ such that v_k has two elements, defined as $v_k = [5] - (v_1 \cup v_2)$.

The girth (or length of the shortest cycle) of the Petersen graph is 5.

Suppose G_p has a cycle of length 3. Since a cycle of 3 would be isomorphic to K_3 , this means there are three disjoint vertices $v_1, v_2, v_3 \in V(G)$, implying that $|v_1 \cup v_2 \cup v_3| = |v_1| + |v_2| + |v_3| = 6$. However, the original set has cardinality 5.

Suppose there were a 4-cycle — this would mean that two vertices share a common neighbor, which we previously showed was not possible in G_p .

Decompositions

A **decomposition** is a list of subgraphs of a graph such that every *edge* appears only once (vertices are allowed to repeat themselves).

A graph is **self-complementary** if it is isomorphic (not equal) to its complement. An n -vertex graph, H , is self-complementary if and only if K_n has a decomposition consisting of two copies of H .

- C_5 is self-complementary because K_5 can be decomposed into two copies of C_5 .
- K_4 can be decomposed into three copies of P_3 .
- $K_{3,3}$ can be decomposed into three sets of pairwise disjoint matchings (where a matching denotes a set of disjoint edges that share no common vertex).
- A k -regular bipartite graph (this will be discussed in section 1.3) will have k perfect matchings.

1.2

Walks, Trails, and Paths

A **walk** is a series of alternating vertices and edges $v_0 e_0 v_1 e_1 \cdots e_{k-1} v_k$. The vertices and edges in a walk can repeat themselves — if a graph is simple, all you need do is list the vertices of a walk.

If $v_0 = v_k$, the walk is closed, else it is an open walk, and the length of the walk is equal to the number of *edges* in the walk.

A **trail** is a walk that does not repeat edges, while a **circuit** is a closed trail. Circuits are usually written in cyclic order, but there is not necessarily any starting or ending point of a circuit.

A **path** is a walk that does not repeat vertices or edges, and a cycle is a circuit that does not repeat vertices.

We can prove the following proposition:

Proposition

Every u, v walk contains a u, v path.

Solution

Let $u, \dots, x, \dots, x, \dots, v$ be a path. If there exists copies of any vertex x , delete all edges and vertices between instances of x and retain one of the instances of x , along with the remaining edges. Continue until there are no repeated instances of any vertices.

Components and Connections

A graph is **connected** if $\forall x, y \in G, \exists x, y$ path. Notice that we said *path*, not necessarily adjacent — obviously if $x \leftrightarrow y$, they have a path between them, but adjacency is not enough to show connectedness.

A **component** is a maximal connected subgraph of any graph.

Maximal vs. Maximum

“Maximum” simply describes the largest set that satisfies the property — for example, if we had a graph where one subgraph was K_4 and there were no subgraphs that were larger than K_4 , we would say that particular subgraph was a *maximum* clique.

Meanwhile, “maximal” describes a property where adding an additional vertex or edge would violate the property. For example, imagine a graph that were K_4 with one vertex adjacent to a vertex that was also adjacent to K_5 . If we started describing K_4 , we would reach a point where adding an additional vertex would make the graph no longer complete — thus, K_4 is a *maximal* clique.

Important for us is that a **maximal path** is one that cannot be extended. This will help us in various proofs later on.

The relation uRv if and only if there is a u, v path in G is known as the **connection relation**, and it is an equivalence relation (reflexive, symmetric, and transitive). The equivalence classes of the connection relation are the components of G .

Edge and Vertex Deletions

If $U \subseteq V(G)$, then $G - U$ is equal to deleting all the vertices in U and the edges incident on the vertices in U , or $G[V - U]$. If $U = \{v\}$, then we denote it $G - v$. An edge deletion doesn’t require deleting the vertices the edge is incident on.

By adding an edge to a graph, we either leave the number of components unchanged or increase them by one, which implies the following proposition.

Proposition

Every graph with n vertices and k edges has at least $n - k$ components.

Proof

Start with n vertices and 0 edges. There are n components in this graph — by adding an edge, we decrease the number of components by 1 or leave them unchanged, thus yielding us that the number of components is at least $n - k$.

A **cut-edge** or **cut-vertex** is an edge or vertex whose deletion increases the number of components in $G - e$ or $G - v$. We can prove the following proposition:

Proposition

An edge is a cut-edge if and only if it is not contained within a cycle.

Proof

This is equivalent to saying that for some connected graph H , $H - e$ is connected if and only if e is in a cycle in H .

Suppose $H - e$ is connected. Then, there must exist a path P in $H - e$ such that $P + e$ is a cycle.

Suppose that e is in a cycle in H . Since H is connected, then $\exists u, v$ path P in H . We then get the two following cases:

- If $e \notin P$, then $P \in H - e$, so $H - e$ is connected.
- If $e \in P$, then without loss of generality, the vertex x appears before the vertex y , and that $e = xy$. We can construct a u, v path as follows: $P = u, \dots, x, y, \dots, v$ in H . Since e is in cycle C , we can create a u, v walk in $H - e$ as follows:
 - Follow P from u to x
 - Follow $C - e$ from x to y
 - Follow P from y to v
- Since every u, v walk contains a u, v path, we have showed that $\exists u, v$ path in $H - e$, so $H - e$ is connected.

Even and Odd Walks

A walk is **even** if it is of even length (as denoted by the number of edges), and a walk is **odd** if it is of odd length. Every closed walk W contains a cycle C if the vertices and edges of C occur in cyclic order as a sublist of W .

Proposition

Every closed odd walk contains an odd cycle.

Proof

We will proceed via induction as follows:

- Base case: if $\ell = 1$, then we know that this is a cycle.
- Inductive Hypothesis:
 - Find a repeated vertex x within W aside from the starting point u itself. That is, $W = u, \dots, x, \dots, x, \dots, u$.
 - If there is no repeated vertex other than u itself, then we have an odd cycle.
 - Else, consider $W' = x, \dots, x$ and $W'' = u, \dots, x, \dots, u$ found by deleting the first instance of x and the remaining edges between that first instance and the second instance of x .
 - We know that since $\ell(W)$ is odd, and $\ell(W) = \ell(W') + \ell(W'')$, we must have that one of $\ell(W')$ or $\ell(W'')$ must be odd.

Proposition

If an edge appears exactly once in a closed walk W , then W contains a cycle through that edge, e .

Proof

Without loss of generality, let $W = y, \dots, x, y$, and $e = xy$. Then, $W' = y, \dots, x$ is a y, x walk, implying $\exists y, x$ path P . Therefore, $P + e$ yields a cycle.

König's Theorem

A graph is bipartite if and only if it does not contain an odd cycle.

In order to prove something *is* bipartite, it is easier to find a bipartition than to show that all cycles in the graph are even.

Proof

Let $\text{dist}(x, y)$ denote the length of the shortest path between x and y , and let G be a connected graph. Let $v \in V(G)$ and $X = \{v \in V(G) : \text{dist}(v, x) \text{ is even}\}$, and $Y = \{v \in V(G) : \text{dist}(v, x) \text{ is odd}\}$, where x is some vertex. Assume towards contradiction that one of either X or Y is not an independent set. Without loss of generality, let X be the set that is not independent. Let $e = x_1x_2$ be an edge for some $x_1, x_2 \in X$. Then, we can construct a path as follows:

- $P_1 = v, \dots, x_1$
- $e = x_1x_2$
- $P_2 = x_2, \dots, v_2$

(\Rightarrow) By our definition, we know that P_1 and P_2 are even, and that $C = P_1 + e + P_2$ is an odd cycle. Therefore, we have shown that every graph that is not bipartite contains an odd cycle.

(\Leftarrow) We can show that every bipartite graph contains an odd cycle since every walk that starts in one independent set X that ends in the independent set X must have even parity. Therefore, all cycles in a bipartite graph must be even.

Graph Unions

The union of a set of graphs G_1, \dots, G_k is defined as follows:

$$V = \bigcup_{i=1}^k V(G_i) \quad E = \bigcup_{i=1}^k E(G_i)$$

Each edge in G can be contained within more than one graph in a graph union, but that is not the case for a graph decomposition.

For example, $K_4 = C_4 \cup C_4$. but K_4 does not decompose into two copies of C_4 since it only contains six edges.

Eulerian Graphs

A graph G is **Eulerian** if it contains a circuit that contains all the edges in G , known as an Eulerian circuit. Vertices may repeat themselves, but edges may not.

Lemma

If $\forall v \in G, d(v) \geq 2$, then G contains a cycle.

Proof

Let $P = u_1, u_2, \dots, u_k$ be a maximal path. Since $d(u_1) \geq 2$ by our assumption, this means u_1 is incident on some edge other than u_1u_2 . However, since P is maximal and cannot be extended, this means u_1 must be incident on an edge that is also incident on $v \in \{u_1, \dots, u_k\}$, implying the existence of a cycle $C = u_1, v, \dots, u_2, u_1$.

Using this lemma, we can prove the following important result about Eulerian graphs:

Proposition

A graph is Eulerian if and only if it has at most one nontrivial component and all vertices are of even degree.

Proof

(\Rightarrow) Whenever we “enter” a vertex during an Eulerian circuit, we also have to “exit” the vertex at an edge. If a vertex is not on the trail, then it has no incident edges and so the vertex is a trivial component. Additionally, if G has multiple components, then there is no trail connecting all components and so G cannot be Eulerian.

(\Leftarrow) Suppose all vertices of G are of even degree and G has only one nontrivial component. Let $e(G) = |E(G)|$

- In the base case, suppose $e(G) = 0$. Then, there is an Eulerian circuit and every vertex is of even degree (namely, 0).
- If $e(G) > 0$, then every vertex in G has a degree at least 2. This means $\exists C \subseteq G$ where C is a cycle. If we delete the edges of the cycle, then the vertices of G have their degree reduced by either 0 or 2, so G retains the property that its vertices are all of even degree. In each nontrivial component of $G - C$, by the inductive hypothesis, they contain within themselves an Eulerian circuit. We can construct an Eulerian circuit by walking along the edges of C , and whenever we reach a nontrivial component of $G - C$, find an Eulerian circuit within each component, then go back along C .

Other Important Lemmas

Even Graphs

Every even graph decomposes into cycles.

Proof

We will proceed via induction as follows:

- If $e(G) = 0$, then we know that this is a cycle (of length zero), so we are done.
- Else, let H be a nontrivial component of G .
 - Every vertex of H has degree at least 2, by our assumption that G is even and H is nontrivial.
 - Therefore, H contains within itself a cycle, C . In $G' = G - E(C)$, we can use the inductive hypothesis on each component of G' . By the inductive hypothesis, we know that G' can be decomposed into cycles, since G' is still even.
 - We add C back into the the decomposition of G' to get a decomposition of G .

Trail Decomposition

For a connected, nontrivial graph with exactly $2k$ odd vertices, the minimum number of trails it decomposes into is $\max\{1, k\}$.

Proof

A non-closed trail contributes an even number of edges within its interior, meaning that we need at least k non-closed trails to handle the $2k$ odd vertices in the given graph. We can pair each vertex with an element in the edge set $\{e_1, \dots, e_k\}$, giving us $G' = G + \{e_1, \dots, e_k\}$ that is connected and even, meaning it is Eulerian.

1.3

Some Definitions

- A graph is k -regular if all vertices have degree k .
- The degree of a vertex, $d(v)$, represents the number of edges incident on the vertex. The maximum degree in a graph G is denoted $\Delta(G)$, and the minimum degree in a graph G is denoted $\delta(G)$.
- The neighborhood, $N(v)$, is the set of all vertices adjacent to v .
- The **order**, $n(G)$, is the number of vertices in G , or $|V(G)|$.
- The **size**, $e(G)$, is the number of edges in G , or $|E(G)|$.

Proposition

$$\sum_{v \in V} d(v) = 2|E|$$

Additionally, each graph has an even number of vertices with odd degree.

Proof

In each graph, the edges incident on a given vertex are incident on another vertex, meaning that summing up the degrees of each vertex means that we are double counting each vertex.

Similarly, since the sum of the degrees of vertices must be even, there cannot be an odd number of vertices of odd degree, or else we would have a fractional number of edges.

The k -dimensional hypercube, Q_k is the simple graph where the vertices are the k -tuples of $\{0,1\}$ and the edges are incident on tuples that are exactly one position different.

The j -dimensional subcube of Q_k is formed by keeping $k - j$ coordinates of the tuples fixed and letting the other j coordinates range along the 2^j tuples. The j -dimensional subcube is isomorphic to Q_j .

We know that Q_k is bipartite because we can create a bipartition where X refers to the tuples with an odd number of 1 elements, while Y refers to the tuples with an even number of 1 elements. We know that X and Y are independent sets, since odd and even numbers differ from other odd and even numbers respectively by 2, so X and Y are a bipartition of Q_k .
